ABSTRACT

Experiom

nts using High Gradient Magnetic Filtration done by the Center

for Energy and Environment Research are discussed. A brief introduction to

this technology and a description of the mobile unit in which field studies
wore performed is presented. Studies to demonstrate the feasibility of the
Process were carried out using sowage from two municipal treatment plants,

EL Conquistador in Trujillo Alto and Guaynabo Treatment Plant. Highest Percent removal in terms of absorbance at 550 nm, Total Suspended Solids (258), Biochemical Oxygen Demand (BOD₅), Total Nitrogen (TN) and Total Phosphorus (TP) were 96.08, 99.4%, 89.08, 66.0% and 98.5%. Average

Optimum concentrations required for HGMP treatment of this waste were 139 g/l of alum, 250 mg/l of magnetite and 25 ml of polyelectrolyte flocculant.

et

Optimum concentrations were higher in the case of the EL Conquistador Plant

Liquid and granular alum as well as a series of different types of polyelectrolytes were also tested,

Electron microscopy studies done on flocculated sewage showed no definite floc-structure as was expected.

Cost estimate analysis for a 100 MGD HGMP plant fabricated by Sala Magnetic

of Boston, Mass. is included along with operational and maintenance cost,

estimates. The advantages of this technique in terms of its low electricity
land requirements added to the exceptional efficiency of the process in
terms of solids and phosphorus removal, makes HGP a highly attractive alter-
native for treatment of the Island's municipal wastewaters.

Description of the Technique

Magnetic Separation techniques are not new, they have been in use since the nineteenth century as a way to remove tramp iron and to concentrate iron ores. The technique depends on the application of a magnetic field to a waste stream causing the material to migrate in the direction of the magnetic field gradient and not under the influence of hydrodynamic forces. Recent years have witnessed the development of 2 new magnetic filtration technologies called high Gradient magnetic filtration (GMP) which is capable of removing microsize particles from a fluid stream at high flow rates. GMP is capable of efficient filtration of very weakly magnetic suspended solids or precipitates for which conventional magnetic separation techniques are ineffective.

?These filters consist of a filamentary ferromagnetic filter bed

(matrix) which is magnetized by a uniform magnetic field producing very high local fields and very high local field gradients in the vicinity of the wire of the matrix. The combination of an efficient magnet and a high gradient matrix allows the economical generation of strong magnetic forces over a large surface area in the magnetic filter bed. Filtration then, may be carried out economically and at process rates of up to several hundred gallons per minute per square foot of fluid stream cross section (gpm/ft²).

---Page Break---

This magnetic filtration technique is not only intended to be used with wastewaters that normally contain magnetic particles, but also can be used to separate very weakly magnetic or nonferromagnetic solid components of the waste stream. The first step is a pre-treatment process in the case of non-magnetic effluents. This pre-treatment is to render the normally non-magnetic components weakly magnetic. Conventionally this step consists of addition of a finely powdered magnetic seed material usually iron oxide to the waste stream, followed by some means to associate the magnetic particles with the non-magnetic or dissolved impurities. The magnetic seed material utilized is generally magnetic black iron oxide (Fe₃O₄)- The fact that Fe₃O₄ is strongly ferromagnetic (its induced magnetization being 408 that of pure iron), that it is

reasonably cheap, that it can be milled to a fine powder, that its surface appears to be a good absorbent material and that it is quite inert in most systems makes magnetite the optimum material for conferring magnetic properties to non-magnetic wastes.

The techniques used to associate magnetite particles with non-magnetic and dissolved materials include three steps: adsorption, coagulation, flocculation and coprecipitation.

Adsorption: In the adsorptive mode magnetite absorbs the non-

magnetic particle or dissolved iron on its surface

Alternatively

magnetite may be adsorbed on the surface of the impurity particle.

---Page Break---

Coagulation: Destabilization of the particles suspended in the fluid as well as reduction of any repulsive forces between the seed and the impurity particles present is accomplished by the addition of inorganic coagulants such as aluminum sulfate (alum). Basically, coagulation is the process in which the particles suspended in a

solvent are destabilized enabling their transport to one another where they may coalesce to larger particles. At the right conditions prevail. Colloid concentration, alkalinity and pH are three factors which affect the process of coagulation during the pre-treatment

Flocculation: High molecular synthetic polymers such as Sarnafloc and Betz are used as flocculants to create bridges and bind together natural flocs thus enhancing the strength of inorganic flocs against shear forces during filtration. Depending on the charge on the ionizable group of a polyelectrolyte they can be classified as being anionic (negatively charged) nonionic (no ionizable group present) or cationic (positively charged). This characteristic - ability to ionize - along with the molecular weight and degree of branching affect the polyelectrolyte's qualities and usefulness in any particular application. With the formation of large, uniform and strongly bound agglomerates the waste is ready to be passed through the high gradient magnetic filter.

Trailer Description

Evaluation of this novel technique in Puerto Rico was done using a 4 Mobile Pilot Plant rented from Sala Magnetics Inc., Cambridge,

Massachusetts. Figure 1 shows the pilot plant as it was stationed

---Page Break---

Magnetic Filtration

Pilot Plant

---Page Break---

at Guaynabo Treatment Plant for on-site research. This trailer was constructed by Relco Corporation of Billerica, Massachusetts, and

was £4

ted with pilot plant components and laboratory facilities by SALA. "The dimensions of this pilot plant are 2.4m Wx 8.5 mL x 3.3 mH with a gross weight of 3,000 kg, @ filtering flow capacity of 380 l/min and a sludge production of 0.5 kg/hr. This mobile laboratory unit was in Puerto Rico for a period of approximately

about months.

Description of the Pilot Plant system

Waste water was pumped into the trailer by a submersible pump and

Passed through a wedge wire screening device (where waste has screened

to 35 mesh size) to prevent clogging of the system lines. The pre-

screened waste was collected in a 55 gallon barrel where it was constantly agitated to prevent any settling of suspended material.

A feed pump forced the waste stream through a rotameter for process.

Real time monitoring and discharged it into a chemical mixing tank.

Before entering this chamber, however, alum was dosed into the

stream by means of a metering pump. Once in the chemical mixing

chamber the pH of the alum-treated waste was monitored and the

dosing rate was adjusted from time to time, as necessary. Magnetite

was added to this tank also using a metering pump. As the seeded

alum-flocs passed into the next treatment tank (flocculating unit)

polyelectrolyte was added to bind the flocs together. In the

flocculating tank slow agitation further increased

fed floc formation.

---Page Break---

The flocculated feed waste was then ready to be drawn through the magnetic separator using a filtering pump. The magnetized flocs as they passed through the separator were attracted and adhered to the

Matrix, The filtered waste passed via a flowrate mo

ring device

land into the disposal line which was provided with an open-funnel to allow sample collection of the filtered waste. Periodically, as the filter cycle was completed (1.0. when flocs no longer adhered to the filter matrix) the 1 liter pump and the magnet were shut off and the matrix was backflushed with high pressure air-water. This backflush water containing the flocs washed from the ferromagnetic fibers was collected into a surge tank from which it slowly drained into a thickener. The sludge which settled at the thickener was manually collected and discarded while the supernatant was pumped back into the flocculating tank. except for the manual adjustment of flowrate

wade at the beginning of a run, plot plant operation was automatically controlled.

Figure 1f shows a picture of the inside of the reactor in which the mixing tank, the flocculating unit, the dark-colored flocculated waste, the electromagnet, the filtered waste and the control panel are clearly evident.

MATERIALS AND METHODS

Preliminary Testing

Preliminary jar testing for determination of optimum concentrations

of magnets

+ alum, and polyelectrolyte took place before any

filtration was attempted, in general the "criterion" for optimum

---Page Break---

---Page Break---

2.2

was based upon the rapidity of formation and precipitation of stable, large, non-stringy flocs and the clarity of the supernatant. Turbidity was measured in terms of absorbance at 550 nm.

Bench studies or "jar testing" as these preliminary studies are frequently designated were done at the laboratory facilities at CEER

or at the trailer during # given filtration, occs

onally, during

oneate experiments the quality of the waste being treated would change during filtration and additional jar testing was necessary

to determine the new optimum concentrations, Usual!

100-ml samples

were utilized for jar testing and optimum concentrations were determined by varying one additive over a wide range of concentrations while keeping the other two constant and adjusting the pH. Alum concentration was the most critical parameter in the municipal sewage treatment undertaken and the pH of the alum-treated waste usually

was optimal between 6.3 and 7.0.

Pilot Plant studies

Pilot plant studies were done on waste produced at two different Sewage treatment plants: El Conquistador and Guaynabo Treatment Plant. Laboratory derived data was applied to the pilot plant operation after deciding on a re-

asonable flowrate (i.e., 11-19 l/min),

Of the waste to be treated. If for example, the optimized alum concentration was determined to be 500 mg/l, a suitable delivery

rate of the premixed alum stock solution was

igned, The alum

stock solution concentration could then be approximately determined

by the equation:

---Page Break---

$C_w = C_u \times \frac{Q_u}{Q_w}$

in which:

USC = Unknown Stock Concentration (g/L)

FW = Flowrate of Waste (l/min)

OC = optimized Concentration (ng/l)

DR = Delivery Rate of USC (l/min)

The stock concentration of the two other additives, magnetite and the polymeric flocculant was also determined in the same fashion.

Water quality parameters such as absorbance at 550 nm, total suspended solids (TSS), biochemical oxygen demand (BOD₅), chemical oxygen demand (COD), total Kjeldahl nitrogen (TKN) and total phosphate (TP), were measured in all samples before and after filtration to determine percent removal of sewage components during the magnetic filtration process. ALL the chemical determinations were done following the procedures described in Standard

Methods (1975). However, there was slight variation in the digestion step for TN analysis. For the first three TW determinations done, digestion was carried out with a prepared digestion agent and glass granules. The rest of the TW determinations was done by adding the digestion chemicals separately and using Hengar granules.

---Page Break---

224

Unfiltered samples from on-site experiments at Guaynabo were a composite of influent collected at the beginning and at the end of the filtration period. Filtered samples were always collected at

the middle of a filtration cycle (i.e., at the midpoint for a 2 minute cycle). To ensure no change in the filtration parameters was done during

a given filtration: samples were collected every 30 minutes and a composite was used for analysis. When a change in a concentration

of a given additive was made in the course of a filtration: additional filtered samples were collected to measure absorbance and check if the variation had produced a noticeable effect. For these cases,

water quality parameters were done on the best filtration obtained

for a given date.

E1 Conquistador treatment Plant

FI Conquistador is an activated sludge treatment plant situated in the municipality of Trujillo Alto having @ capacity of 0.5 MoD

land an actual process rate of 0.1 mop"), Raw sewage from this treatment plant was collected on several occasions for magnetic separation while the trailer was stationed at CFER parking facilities. A maximum of 346 Liters of raw sewage was filtered on any given occasion, It was unfortunate that in only three cases sample were collected and actually stored for later analysis to determine the relative success of the filtration process at a time, However, extensive jar testing of the wastes was performed. The maximum

Filtering flowrate tested was 11 L/min with filter cycles Lasting

---Page Break---

u

} minute. The total filtering time was approximately 30 minutes.

Water as used in all cases.

Granular alum and Kercoflo 631 were utilized in all the filtrations.

Optimum concentrations of alum, magnetite and polyelectrolyte were of the order of 50 mg/l, 400 mg/l and 3 mg/l, respectively for all

No attempt was made to vary these concentrations during the

Filtrations.

Guaynabo Treatment Plant

Onsite Filtrations were done at the Guaynabo Treatment Plant for a period of two months starting March 21, 1960 and ending on May 22,

1980, Guaynabo is a trickling filter treatment plant with a total filtering capacity of 1.9 MoD but with an actual average Flow of

2.5 neo?)

?There is also present at this treatment plant an activated sludge package treatment facility which treats part of the incoming waste. Table I gives the pilot plant parameters used for the 18 filtration runs made at Guaynabo. As can be observed two types of waste were used: raw sewage and the waste after it had gone through the preliminary clarifier. Filtering flowrates were of the order of 11 l/min, 15 l/min and 19 l/min, and the magnet delay time was varied from 4 to 6 seconds:

?The Longest continuous

filtering operation was of 21/2 hours:

A 2,5 kG magnetic field

was used for all tests. Two types of alum were utilized, granular and Liquid. A number of different polyelectrolytes ranging from

anionic to nonionic and cationic were also tested to determine their

effectiveness. The high molecular synthetic polymers tried during

actual filtrations were the following:

---Page Break---

---Page Break---

---Page Break---

ete 1420, 1120, 1129 and 1140; Hercofloc ?18, 827 and 831; and
Percol 720, 720, 126 and 776. Testing of these polymers was done
after the pilot plant system vas standardized in terms of the

optimum concentrations of alun, magnetite and Hercofloc 831. After

esting of @ given polymer wae completed the system was again brought back to ite conventional operational configuration using Hercofloc 831, This was done in crder to recheck the system and be sure that the concentration requirements for the waste had not changed during ?the testing period. Each testing period lasted about 30 to 45 minutes at the end of which samples were collected for absorbance determinations. Polymer concentrations tested ranged from 1.0 to 1.5 ma/l, the highest concentration giving the best results. Efficiency of any given polymer was rated by the ? absorbance seduction at 550 nm which in most cases was related to the type of flees formed.

Granular and Liquid alun concentrations were varied from 63 s/t ?ko 190 mg/l, 130 ng/2 giving, on the average, good results. Magnesite was changed from 1000 ng/1 to 100 mj/1, with a concentration of 250 mg/l giving as good results as higher concentrations. Concentrations of Nercofloc 831 were varied from 20 ne/l to 1 mg/l, with 1.5 mg/L giving as good or better resslts as higher concentraticns.

?the ELltering cycle period of 2 minutes was selected on the basis of the quality of the filtered vaste produced through experimentation. Figure TIT shows the effect of time into cycle versus absorbance at SSdnm. Ae can be deduced from this graph, a 2 minute filtering cycle was most adequate if a good filtrate quality was desired. after

about three minutes into the filtering cycle the matrix began to saturate with trapped material and was unable to attract and

| consequently, the filtration efficiency

decreased rapidly, Experiments done by increasing the concen

tration of magnetite with the hope of increasing the 2 minute filtering cycle were frustrated by the quantity of solids which the matrix was called upon to maintain magnetically bound.

?The volume of backflush produced was measured in order to obtain an estimate of the volume backflushed per volume treated, The back~

flushed volume for a 2 minute cycle)

at a filtering rate of 19 l/min

was found to be of the order 3.

Liters. So the ratio of backflush

volume to treated volume was about 0.1. With increasing Filtering

Fates the ratio of backflush volume to treatment volume increased

proportionately. Unfortunately, the amount of the supernatant being returned to the flocculating tank after the backflush went to the thickener was not measured, This will undoubtedly make this concentration ratio much more favorable.

Electron Microscopy studies

Studies to investigate the structure of the flocs formed and the relationship between floc morphology and removal of suspended material were attempted using electron microscopy. Due to the characteristics of the materials under study the samples had to be agar-embedded to facilitate their handling during the preparation process. Since flocs are the result of the interaction of different components such as alum, magnetite, polymer, and the flocculated

---Page Break---

material, it was found necessary to look at each individual component in order to get a clearer picture of the floc's morphology. Alum (granular and Liquid), magnetite and Hercfloc 831 were processed for analysis. These filtration additives were prepared in concentrations equal to the ones used under normal flocculation as well as in more concentrated forms. Centrifuged samples of primary treated

Sewage and of raw sewage were also analyzed. Flocs formed by the

addition of alum and Hercfloc 831 in the presence of water and in

the presence of raw sewage were also created.

Preparation of Samples

centrifuged waste and flocs containing raw sewage were fixed at room temperature in either 2.5% or 3.0% glutaraldehyde (prepared in water or 0.1 M phosphate buffer). The pH of the glutaraldehyde

solution was kept around pH 7.0. Fixation varied from 1 to 2

hours. This procedure was followed by three rinsing periods of five minutes each. Rinsing was done with water or phosphate buffer. At this point the organically-fixed material as well as the non-fixed inorganic samples were embedded in a 4% agar solution (in phosphate buffer) and the blocks thus formed were allowed to harden. A block containing just agar was also included in the process. ALL the blocks were sliced into pieces measuring 1 mm or less and post-fixed in 1% OsO₄ (prepared in 0.1 M phosphate buffer at pH 7.0) at room temperature for 1 to 2 hours.

Dehydration was done after post-fixation with 0% and was

plished by the use of a graded series of alcohols (50%-70%-80%-95%-

---Page Break---

8

100%) followed by 100% propylene oxide. Dehydration was also done at room temperature,

Following dehydration the samples were placed in a solution of propylene oxide and resin and were left overnight uncapped to

done

allow the propylene oxide to evaporate. Infiltration was

by placing the samples in the

resin mixture for a period of 2 to 6

Two types of resin mixtures were most commonly used as the embedding medium. The first resin mixture consisted of 100 parts of a resin (LK 112), 89 ml of a hardener (NADIC methyl anhydride) and

1.5% of the accelerator (benzyl dimethylamine). The other resin

Mixture used followed the same formulation except that another

resin (Epon 12) was utilized, once infiltration was completed,

each piece of infiltrated material was placed in a gelatin capsule

which was then filled up with the resin mixture. The capsules were

placed in an oven at 60°C for 2 to 3

5 days to allow the embedding mixture to polymerize. Blocks thus formed were allowed to cool and the gelatin cover was removed in warm water, Trimming and sectioning of the blocks was done using an ultramicrotome. sections of about 100 A thickness were placed on 300 mesh size copper grids and stained for five minutes in 14 uranyl acetate, rinsed in water, and placed for 5 extra minutes in an alkaline solution of lead acetate. Once dried, the grids were ready to be viewed with the electron microscope,

El Conquistador Treatment Plant Data

?The extent of elimination of contamination By magnetic filtration
an raw sewage coming from El Conquistador Treatment Plant in Trujillo

Alto is given in Table TZ, The optimum average removal for this waste in terms of absorbance, 785, 80D, and TP was of the order of 95.98, 91.7%, 71.98 and 87,38 respectively. The highest percent reductions for this waste in terms of absorbance, 785, B00, and oP were as follows: 96.2%, 95.4%, 88.1%, and 98.5%. Concentrations

of alun, magnetite and Hercofloer 931 needed on this waste for filtra-

tion were of the order or 550 ng/l, 400 ng/l and 3 mg/l, respectively.

Suayrabo treatment Plant pata

?Table IIT gives the measured water quality values of raw sewage and land primary treated sewage before and after magnetic filtration treatment and the percent improvement achieved by the process.

Average treatment values for raw sewage in terms of absorbance, 755, BOD, TN and TP removal were 88.2%, 59.2%, 71.7%, 53.9% and 69.9% respectively. The best separation obtained for this waste was characterized by a decline in the paraneters measured of 96.09 of

absorbance, 99.48 of TSS, 89.0% of BOD, 66.0% of TH and 98.5% of TP.

26

Average % removal for primary treated sewage in terms of absorbance, 80, COD, TN, and GP were of the order of 85, 55.38, 52.3%, 51.5% and 96.68 respectively. For the primary treated sewage the highest percent removal in terms of absorbance, TSS, 80D, COD, 1N and TP

were of the order of 90.88, 87

08, 68.9%, 66.4%, 52-68 and 99,67

respectively.

Visual observations of the sewage entering the plant on dry, sunny days was strikingly different from that entering on rainy days.

This change in effluent could also be noticed in a change in the requirements of alum for good floc production. Alum proved to be the most critical and variable of the chemicals used for magnetic flocculation, the quantity required for a good, rapid precipitation of curdy flocs, varied from as low as 90 mg/l to as high as 190 mg/l.

for the average, for Guaynabo, alum concentrations of 130 mg/l gave positive results. Granular versus liquid alum made no difference

in the requirement of alum needed for filtration, However, Liquid alum was much easier to handle than the granular form.

Magnetite concentrations as high as 1000 mg/l and as low as 100 mg/l were tried; but it was shown that 250 mg/l was enough for a good filtration to take place. Concentrations higher than 250 mg/l did not improve the filtration and did not lengthen the cycle as had been expected a priori. Concentrations of 160 mg/l and lower resulted in a lot of flocculated material escaping the attraction of the magnetic matrix. This was probably due to the decreased incorporation of the magnetic particles in the floss. It is interesting

---Page Break---

to note, however, that on the average a magnetite concentration equal to 1.6 times the concentration of suspended solids present was sufficient for an acceptable filtration, This is far lower than the conventional recommended dose rate which is about 3 times the concentration of 758.

Ptercoftoc 31, a synthetic polymer was the polyelectrolyte utilized

in all filtration experiments conducted over an extended period. A number of other polymers were also tested, but always for periods of time shorter than 1 hour. Concentrations of this moderately anionic polymer ranged from as high as 20 mg/l to as low as 1.0 mg/l, It was observed that @ 1,5 mg/l concentration gave as good results as higher concentrations, while at concentrations as low as 1.0 mg/l the agglomerations formed were not large and yielded easily to disruption from hydrodynamic forces. Of the rest of the polymers tested only two produced good-sized flocs and the filtrate in each case showed a Generally higher absorbance value than did the filtrate using Hercofloc S91. With the highly anionic setz 1120 @ xeduction in absorbance of 97.38 was observed and a percent reduction in BoD of 77.8 was obtained, ?The moderately anionic Betz 1110 produced a reduction of absorbance of 72.28 and large flocs. It should be pointed out that all these Polymers were tested at pi's which did not require adjustment (i.e. between 6.3 - 6.5).

Electron Microscopy Studies

HMectron microscopy work was hindered from the beginning by a

ries of problems related to the incomplete polymerization of the

resin mixture which in turn made the task of sectioning the blocks

---Page Break---

almost impossible. In order to correct this problem a number of changes were made during the research such as increasing the polymerization time, using one anhydride, nadic methyl, instead of two, and trying two different epoxy resins, Lx 112 and Epon 612. These changes made no significant difference in the quality of the blocks produced and therefore in most instances few good sections or none at all were obtained for viewing under the electron microscope. Also, samples containing magnetite had to be discarded due to the fact that the magnetite present on these blocks tended to rupture the sections as they were cut.

Samples that could be =

In under the electron microscope were those of agar, alum, polyelectrolyts, centrifuged raw sewage and flocculated raw sewage. Samples of the additives that were analyzed showed no particular or repetitive pattern that could be attributed to their presence. In other words, from the work done it was

impossible to distinguish the

three different additives from one

another. As was expected, a great number of micro-organisms, believed

to be bacteria, were present in the centrifuged raw sewage as shown in Figure IV. A close up of the micro-organisms present in raw

sewage is seen in Figure V. Bacteria were also present in samples of flocculated raw sewage but these organisms were randomly distributed and not within a structural floc-type form as was envisioned

by the investigators. An example of this is seen in Figure VI,

cost ANALYSIS

Capital costs

?The estimated installed capital costs for a High Gradient Magnetic Filter based on a 1 MGD Sewage Treatment Facility was calculated by staff engineers of Sala Magnetics and ranges between \$660,000 and \$725,000, This plant would be a fully-automatic, self-contained wastewater treatment unit. It would incorporate pre-treatment. (screening and egriteing), studge dewatering, and magnetite

Jed recovery sub-

systems in addition to the basic mag-soed process, ?The solids operation Le, sludge dewatering and magnetite reclanation, would function

during @ single shift only and chemical storage facilities would permit 12 20-day uninterrupted operation period. The control systems would allow continuous operation requiring only a daily operation inspection. This plant would have @ back-up system for units critical to process function. The estimated cost includes standard instrumentation and data logging equipment but the cost of Land has been excluded due to

At site-specific nature.

Operational and Maintenance Costs

Table IV shows operational and maintenance costs for the INGD seeded water treatment plant, Estimates are in dollars per 1000 gallons of water treated, From this table it can be seen that the total chemical, electrical and maintenance and operator labor costs per 100 gallons are in the order of 0.20, 0.13, 0.08 and 0.12 respectively. It should be

noted, however, that electrical costs can be reduced up to 50% by judicious

(CONCLUSIONS)

UGMP was shown to be more efficient when used to treat raw sewage than in applications involving treatment of primary-treated sludge.

Highest percent reductions of absorbance, TSS, BOD, Tt and TP obtained with this technique during on-site filtration were 96.2, 99.4%, 89.7, 66%,

and 98.5% respectively. In most cases, optimum concentrations of

additives for treatment were 130 mg/l of alun, 250 mg/l of magnetite

and 2.5 mg/l of polyelectrolyte. Anionic polymers such as Hercofloe

831 and Betz 1120 proved to be the best synthetic polymers tested for

treating sewage. A continuous monitoring system for adjusting optimum

alun levels is necessary:

wry for treating this waste which was found co

vary in quality as a function of weather conditions.

Results of the pilot plant studies demonstrate that IGMP is viable

method for the purification of raw sewage in terms of the efficient

removal of suspended solids and TP, Even though seed reclamation

studies were not attempted and comparison of the costs!

effectiveness

of this technique versus conventional methods were not done by CFER,

?the economic viability of this process as described by Oder and Horst?

?shows HMF units of 10 MoD or better to be economically competitive,

Also HGH has the important advantages of low power requirements and

low real-estate costs due to its high processing rates and the compact-

ness of the filtering machinery. The ever-increasing cost of power

and the high cost of available land in Puerto Rico added to the demons:

trated effectiveness of the technique should make HOM a highly attractive

treatment alternative for the Island's municipal wastewaters.
